Slide 1

Photosynthesis

Source: HuggingFace wikipedia/wikipedia (Simple English, 2023-11-01)

URL: <https://simple.wikipedia.org/wiki/Photosynthesis>

Photosynthesis is how plants and some microorganisms make carbohydrates. It is an endothermic (takes in heat) chemical process which uses sunlight to turn carbon dioxide into sugars. The sugars are used by the cell as energy, and to build other kinds of molecules. Fundamentally, photosynthesis converts light energy into chemical energy.

Photosynthesis is vital for life on Earth. Before photosynthesis, Earth had no free oxygen in its atmosphere.

Slide 2

Green plants build themselves using photosynthesis. Algae, protists and some bacteria also use it. Some exceptions are organisms that directly get their energy from chemical reactions; these organisms are called chemoautotrophs.

Slide 3

Origin of photosynthesis

Photosynthesis is not an accident. It happens because its building blocks occur naturally in space, and get included when planets form. We have no idea as to how common or rare this process is. We do know that higher elements are formed in supernovae, and that is the origin of all elements higher than helium. The higher elements found in Halley's Comet have been analysed.

Slide 4

Before photosynthesis, the Earth's atmosphere had almost no oxygen. Even without oxygen, some simple life-forms could have existed. But the key event for life as we know it was the Great Oxygenation Event.

Ways it is done

Photosynthesis can happen in different ways, but there are some parts that are common.

Slide 5

carbon dioxide + water + light energy $\rightarrow$ glucose + oxygen

Carbon dioxide enters the leaf through the stomata by diffusion from the atmosphere.

Water is absorbed from the soil by root hair cells, which have an increased surface area adapted for their uptake of water.

Photosynthesis occurs in the chloroplasts in leaves (or other green tissues). They contain chlorophyll, the green pigment that absorbs light energy. In leaves, palisade cells have chloroplasts to capture light.

Slide 6

Oxygen is produced as a result of photosynthesis and released into the atmosphere through respiration. All the oxygen in the atmosphere has its origin in plants (including those microorganisms which do photosynthesis). Glucose is used in respiration (to release energy in cells). It is stored in the form of starch (which is converted back to glucose for respiration in the dark). Glucose can also be converted into other compounds for growth and reproduction e.g. cellulose, nectar, fructose, amino acids and fats.

The process

Slide 7

Photosynthesis has two main sets of reactions (phases). Light-dependent reactions which need light to do work; and light-independent reactions which do not need light to do work.

Light-dependent phase

Light energy from the sun is used to split water molecules (photolysis). The sunlight hits chloroplasts in the plant. This causes an enzyme to split the water. Water, when split, gives oxygen, hydrogen, and electrons.

Slide 8

Hydrogen, along with electrons energized by light, converts NADP into NADPH which is then used in the light-independent reactions. Oxygen gas diffuses out of the plant as a waste product of photosynthesis, and ATP is synthesized from ADP and inorganic phosphate. This all happens in the grana of chloroplasts.

Slide 9

Dark phase

During this reaction, sugars are built up using carbon dioxide and the products of the light-dependent reactions (ATP and NADPH) and various other chemicals found in the plant in the Calvin Cycle. Therefore, the light-independent reaction cannot happen without the light-dependent reaction. Carbon dioxide diffuses into the plant and along with chemicals in the chloroplast, ATP, and NADPH, glucose is made and finally, transported around the plant by translocation.

Factors affecting photosynthesis

Slide 10

There are three main factors affecting photosynthesis:

Light intensity

Carbon dioxide concentration

Temperature

Light intensity

If there is little light shining on a plant, the light-dependent reactions will not work efficiently. This means that photolysis (breakdown of water by light) will not happen quickly, and therefore little NADPH and ATP will be made. This shortage of NADPH and ATP will lead to the light-independent reactions not working as NADPH and ATP are needed for the light-independent reactions to work.

Slide 11

The light intensity required is easily investigated in an aquatic plant such as pondweed. The oxygen bubbles given off can be counted or the volume measured. By changing the distance between light and plant, the light intensity is made to vary. Change in light intensity will affect the change in rate of photosynthesis. Artificial lighting can be used in the dark to maximise the photosynthetic rate.

Slide 12

Carbon dioxide levels

Carbon dioxide is used in the light-independent reactions. It combines with NADPH and ATP and various other chemicals to form glucose. Therefore, if there is not enough carbon dioxide, then there will be a build-up of NADPH and ATP and not enough glucose will be formed.

Slide 13

Temperature

There are many enzymes working in photosynthetic reactions – such as the enzyme in photolysis. All enzymes work best at their optimum temperature. All light-dependent and light-independent reactions will occur normally at average or optimum temperatures. Tropical plants have a higher temperature optimum than the plants adapted to temperate climates.

When the temperatures are too low, there is little kinetic energy, so the reaction rate decreases. If the temperatures are too high, the enzymes become denatured and the catalysis of photosynthesis reaction stops.

Slide 14

Greenhouses must keep an optimum temperature for normal functioning of plants.

Early evolution

The first photosynthetic organisms probably evolved early in the history of life. They may have used reducing agents such as hydrogen or hydrogen sulfide as sources of electrons, rather than water. Cyanobacteria appeared later, and the excess oxygen they produced caused the oxygen catastrophe. After this, the evolution of complex life was possible.

Slide 15

Differences

The photosystems of green sulfur bacteria and those of cyanobacteria, algae, and higher plants are not the same. That shows photosynthesis occurred not once, but several times over.

Effectiveness

Today, the average rate of energy capture by photosynthesis globally is about 130 terawatts. This is about six times larger than the current power used by human civilization.

Photosynthetic organisms also convert about 100–115 thousand million metric tonnes of carbon into biomass per year.
